# Lightweight and flexible: developing industrial robots in timber construction

## About this project

### Context

or the handling of workpieces. The supporting structures of these articulated robots are usually made of cast aluminium or steel. This design is heavy, energy-intensive to manufacture and is particularly worthwhile for large quantities with consistent geometries.

At the same time, there is a growing demand for robots whose dimensions and reach can be customised to specific applications. Rigid modular systems and long development times make this individualisation difficult.

Wood-based materials offer an alternative here: they are lighter, store CO<sub>2</sub> and can be flexibly processed using panel-based concepts and manufacturing processes based on computerised numerical control (CNC). This is where the researchers in the InRoHo project come in. They are investigating how load-bearing structures for industrial robots can be built from wood-based materials.

### Purpose

The researchers want to develop an articulated-arm robot in a wooden design whose performance is equivalent to established metal structures. The focus is on a significant reduction in weight, a better carbon footprint and economical production, even in small series.

The project team is aiming for a modular lightweight timber construction, in which the load capacity, reach and geometry can be flexibly adapted to different applications. By substituting metal structural components and utilising renewable raw materials, the aim is to reduce greenhouse gas emissions in production and operation.

At the same time, the wood-based structure should improve movement and positioning accuracy thanks to its damping properties, thereby contributing to the productivity of automated systems.

# Lightweight and flexible: developing industrial robots in timber construction

## About this project

### Procedure

The project team is initially developing a variably configurable modular system for robot elements made from panel-shaped wood materials. This forms the basis for lightweight designs that are manufactured using established CNC technology. Tests on components, connections and assemblies provide characteristic values for dynamic behaviour, fatigue strength and climate-related influences.

At the same time, the scientists are adapting the drivetrain and the control system to the changed system behaviour. In tests, they evaluate the positional accuracy, repeatability and motion stability of the overall system under laboratory and operating conditions. The results are incorporated into the design, calculation and control until a near-series prototype is available.

Finally, the researchers compare the ecological impact of the wooden construction method with conventional metal robots and derive basic principles for small series in industrial practice.
